LARGE-SCALE WIND-TUNNEL INVESTIGATION OF THE LOW-SPEED  
AERODYNAMIC CHARACTERISTICS OF A SUPERSONIC TRANSPORT  
MODEL HAVING VARIABLE-SWEEP WINGS\*

By Anthony M. Cook, Richard K. Greif, and Kiyoshi Aoyagi  
Ames Research Center

SUMMARY

The results are presented as six-component aerodynamic force and moment data obtained at various angles of attack and sideslip. Data were obtained at a Reynolds number of 16 million, based upon the mean aerodynamic chord of the wing swept to  $75^\circ$ . The investigation included variations of wing sweepback and aspect ratio, leading-edge slat deflection and geometry, trailing-edge flap deflection, geometry, and span extent, and horizontal-tail geometry.

The results show that all configurations tested, except one, were longitudinally unstable at high lift. The configuration that was not unstable had a tail in a low horizontal position, a wing sweepback angle of  $25^\circ$  with a large portion of the fixed wing deflected as a leading-edge flap.

INTRODUCTION

The development of any supersonic aircraft involves combining aerodynamically incompatible high- and low-speed design requirements. The variable-sweep wing concept is one approach to this problem. One basic requirement in this approach is to provide acceptable stability characteristics by minimizing the aerodynamic center shift due to wing sweep.

Earlier concepts of variable-sweep wings (ref. 1) incorporated a longitudinal translation of the wing together with change in sweep angle to eliminate the aerodynamic center shift associated with changing sweep. Efforts to avoid the mechanical difficulties inherent with longitudinal translation of the wing resulted in the concept of the fixed outboard pivot and a fixed, highly swept, inboard wing section designed to minimize aerodynamic center shift (refs. 2 through 6). Small-scale results give evidence of longitudinal instability characteristics at the stall for the high-lift configurations of this design. The purpose of the tests reported herein was to investigate this longitudinal instability and the maximum lift characteristics of high-lift, variable-sweep configurations at high Reynolds numbers.

The scope of this investigation was limited to the first-order effects of the variables considered most important: wing sweep in low-speed cruise and

high-lift configurations, wing aspect ratio, trailing-edge flap systems, leading-edge slats, horizontal-tail area and location, and fixed-wing leading-edge radius and flaps.

## MODEL AND APPARATUS

### Description of Model

The basic model consisted of a low-wing, variable-sweep transport configuration. Various wing leading-edge sweepback angles ranging from  $13\text{-}1/2^\circ$  to  $75^\circ$  were tested. Four configurations are shown installed in the wind tunnel in the photograph of figure 1: two high-aspect-ratio configurations, with low and high horizontal-tail positions (configurations  $A_1$  and  $A_2$ , respectively); and two low-aspect-ratio configurations, with high and mid horizontal-tail positions (configurations  $B_1$  and  $B_2$ ).

The wing pivot was located at 36-percent semispan and 46-percent chord of the fully swept wing (based upon the low-aspect-ratio wing of configuration B). The fixed portion of the wing was provided with either  $70^\circ$  or  $75^\circ$  leading-edge sweep.

### Planform Geometry

Geometric details of the high-aspect-ratio configuration (A) and the low-aspect-ratio configuration (B) can be found in tables I and II, respectively. A sketch including pertinent dimensions of the model is shown in figure 2.

The airfoil section for the movable wing had a flat lower surface and the thickness distribution of an NACA 65A006 airfoil section. See table III for wing airfoil coordinates.

The lower aspect ratio of configuration B was obtained by removing  $3\text{-}1/2$  feet of wing tip from configuration A.

Fixed-wing section geometry is detailed in figure 2(c) by cross sections at various fuselage stations. Planform details are given in figure 2(d). The basic leading edge was sharp along its entire length. However, an alternate, rounded leading edge shown in figure 2(e) was also tested. This rounded leading edge tapered from a radius of 3 inches at the fuselage juncture to 0.75 inch (wing leading-edge radius at movable-wing juncture).

The fuselage consisted of a blended wing-body section, as shown in figure 2(c), with an underslung, side-by-side engine nacelle with plugged, two-dimensional inlets faired to the rectangular aft fuselage shown in figure 1.

### Horizontal Tail

The horizontal tail was tested in three positions (see fig. 2(b)): low, mid, and high. In the low position it was mounted on the fuselage at 10 percent  $\bar{c}$  (of  $25^\circ$  sweep) below the wing-chord plane; in the mid position it was mounted on the vertical stabilizer at 10 percent  $\bar{c}$  above the wing-chord plane; in the high position it was also mounted on the vertical stabilizer,

at 50 percent  $\bar{c}$  above the wing-chord plane. Because of the sweepback of the vertical stabilizer, horizontal-tail length ( $l_T$ ) varied for the three positions. Two horizontal-tail sizes were tested in the high position.

For all tests of configuration  $A_1$ , the low tail was at a negative dihedral of  $10^\circ$ .

### High-Lift Devices

Fixed-wing high-lift devices.— Details of the plain flap of the fixed wing are shown in figure 2(d).

A simulated Krüger type flap was tested on the leading edge of the fixed wing, with both sharp and rounded fixed-wing leading edge (see fig. 2(e)).

Movable-wing trailing-edge double-slotted flap system.— The double-slotted flap geometry and a typical cross section are shown in figure 2(f). The vane was  $7\frac{1}{2}$  percent of the wing chord, streamwise, with the wing at  $25^\circ$  sweep. The main flap comprised 25 percent of the wing chord. A slot of 2-percent wing chord was maintained at the vane. Flap deflections ranged from  $30^\circ$  to  $60^\circ$  in  $10^\circ$  increments. The slot geometry was modified to improve flap performance. The modification (fig. 2(f)) consisted of adding sheet metal extensions to the wing trailing-edge shroud and vane and was used for all tests of double-slotted flaps unless otherwise noted.

Movable-wing trailing-edge single-slotted flap system.— The single-slotted flap configuration was achieved by removal of the vane of the double-slotted flap and moving the flap forward into the wing. This reduced the wing chord by 4 percent and accounts for the difference in wing area and aspect ratio between the two flap systems. A slot of 2-percent wing chord was maintained at all flap deflections, and the range of flap deflection was from  $0^\circ$  to  $30^\circ$ ,  $40^\circ$ , and  $50^\circ$ . The geometry and cross-section details of this flap system are given in figure 2(g).

Both flap systems were constructed in three sections, extending (as shown in fig. 2(a)) from 20 to 52 percent semispan, from 52 to 67 percent semispan, and from 67 to 98 percent semispan of the high-aspect-ratio wing. As a result, flap deflection notation is indicated in three parts:

$\delta$  = inboard deflection/middle deflection/outboard deflection

Movable-wing leading-edge slats.— The details of leading-edge slat size, deflection, and positioning are shown in figure 2(h). Two sized slats were tested, one having a length equal to 15-percent streamwise wing chord (at  $25^\circ$  sweep), and the other,  $18\frac{3}{4}$ -percent wing chord. The profile of the 0.15c slat was made to match the leading-edge profile of the wing. The 0.1875c slat incorporates the basic 0.15c slat with a rounded leading-edge extension to provide camber as shown in the figure. Slat deflection,  $\delta_s$ , is given relative to its undeflected position as if it were "gloved" onto the

wing. Slat gap,  $g_s$ , was varied from 0- to 2-percent chord in 1/2-percent increments. Unless otherwise noted, all slat data reflect the use of the basic slat of 0.15c length.

## TESTING AND PROCEDURE

Six-component force and moment data were obtained by conventional wind-tunnel testing methods through an angle-of-attack range from  $-4^\circ$  to  $+22^\circ$ , and an angle of sideslip from  $-12^\circ$  to  $+4^\circ$ . Free-stream dynamic pressure was 15 pounds per square foot, corresponding to a Reynolds number of 16 million, based upon mean aerodynamic chord at  $75^\circ$  wing sweep.

The majority of tests were directed toward the development of high-lift devices and the investigation of longitudinal stability characteristics for landing and take-off configurations.

## REDUCTION OF DATA

### Corrections

Standard corrections were applied to angle of attack to account for wind-tunnel wall effects. The corrections accounted for the variations in span due to wing sweep. Measured drag was corrected in accordance with the angle-of-attack correction. In addition, the following correction was added to drag measurements to account for strut tares:

$$\Delta C_D = 0.0036$$

No  $\Delta C_m$  correction was made for tunnel-wall corrections for tail-on conditions due to the variable-sweep nature of the configuration.

### Reference Dimensions

The computation of force and moment coefficients for all wing sweeps of a given configuration was based on the dimensions corresponding to the total wing area, including fixed wing, at the  $75^\circ$  sweep condition of that particular configuration.

### Moment Center

The moment center for all configurations, regardless of wing sweep, was taken on the axis of the wing pivot, 2.875 inches above the wing-chord plane.

## RESULTS

The acquisition of data for this investigation covered four testing periods and the several configurations previously mentioned. The results in figures 3 through 48 present longitudinal characteristics and selected cases include lateral-directional characteristics. These results are summarized in figures 49 through 56 and are discussed more completely in the Discussion section of this report. Table IV is a complete index to the figures.

## DISCUSSION

### General Characteristics

Aspect ratio.— Figure 49 presents a comparison of the test data for wings of aspect ratio 6.9 and 8.4 at  $25^\circ$  of wing leading-edge sweepback and with high-lift devices installed. At  $12^\circ$  angle of attack, for instance, there is an incremental loss of 6.5 percent  $C_L$  in reducing aspect ratio from 8.4 to 6.9, accompanied by a decrease in stability of 5-percent static margin. The reduction in aspect ratio causes a lower lift-curve slope, but it is shown that for this degree of wing sweepback, there is essentially no difference in  $C_{L_{max}}$ .

Wing sweep.— Figure 50 shows the effects of  $13\text{--}1/2^\circ$  and  $25^\circ$  wing sweep for both the flaps-up and flaps-down conditions. In the case of  $40^\circ$  flap deflection, it is seen that there is no appreciable benefit to be derived by a wing sweepback angle of less than  $25^\circ$ , in terms of a "usable"  $C_{L_{max}}$ , or that  $C_L$  at which pitch-up occurs. Changes in lift due to wing sweep for the flaps-up condition are also very small. Note that the aerodynamic-center shift due to wing sweep from  $13\text{--}1/2^\circ$  to  $25^\circ$  with flaps up amounts to 8-percent static margin and is essentially the same as the change in static margin due to  $40^\circ$  of flap deflection at  $13\text{--}1/2^\circ$  of wing sweep. (The static margin change due to flap deflection, however, is a result of the downwash flow at the particular horizontal-tail location, since no change is indicated in the tail-off data of figs. 36 and 37.)

### Longitudinal Stability

As mentioned in the Introduction, variable-sweep configurations generally have unstable pitching-moment characteristics at high lift coefficients. The reason is that a wing-tip stall progressing inboard (based on tuft observations) is further aggravated by a vortex generated along the highly swept leading edge of the fixed wing delaying inboard stall. The size and sweep of the fixed-wing portion contribute to the strength of this vortex. Part of this investigation involved testing horizontal-tail positions in combination with various flow control devices in order to alleviate this problem.

Effect of fixed wing.- Figure 24 shows that reducing fixed-wing leading-edge sweepback from  $75^\circ$  to  $70^\circ$  increases longitudinal stability approximately 7 percent and correspondingly increases maximum lift coefficient by 7 percent.

Effect of horizontal tail.- Figure 51 summarizes the effects of horizontal-tail location and size on pitching moment. The only tail position that gave reasonably linear pitching moment up to high lift coefficients was the low position, located 10 percent of the  $25^\circ$  sweep  $\bar{c}$  below the wing-chord plane. Placing the tail at a high position (50 percent  $\bar{c}$  above the wing-chord plane) caused a severe pitch-up at lift coefficients of 1.4. The tail midway between the high and low positions was somewhat better than the high tail position, but the longitudinal characteristics were still unsatisfactory.

Figure 52 presents the control effectiveness ( $\partial C_m / \partial i_T$ ), for two of the horizontal-tail configurations just discussed, and effective downwash angle ( $\epsilon_{av}$ ) and tail angle of attack ( $\alpha_T$ ) for the tail in the high position. These curves were obtained from cross plots of pitching moment versus angle of attack for various values of tail incidence. It is shown that, for both tail positions, the  $\partial C_m / \partial i_T$  curve has virtually no change in slope up to  $12^\circ$  angle of attack, indicating no change in tail efficiency factor. However, above  $12^\circ$  angle of attack for the high tail, the changing downwash field causes the tail angle of attack ( $\alpha_T$ ) to fall back to zero at  $16^\circ$  wing angle of attack so that the stability contribution of the tail is lost. This effect is primarily due to the vortex generated by the fixed-wing leading edge. At the same time, above  $12^\circ$  wing angle of attack, there is a reduction in control power ( $\partial C_m / \partial i_T$ ) for the high tail, indicating a reduction in dynamic pressure at the horizontal tail. On the other hand, the low tail is not adversely affected by the wing downwash field (as illustrated by increasing  $\partial C_m / \partial i_T$ ) above  $12^\circ$  angle of attack.

Flow-control devices.- Reduced fixed-wing sweepback and certain flow-control devices on the fixed-wing leading edge were effective in alleviating the reduction of longitudinal stability at high angles of attack. Figure 53 shows the effects of these control devices on pitching moment. With the tail in the low position, deflecting a large portion of the fixed wing about a hinge line along the fuselage juncture (similar to a plain leading-edge flap) essentially eliminated the unstable pitching moment break at the stall. A Krüger flap used with a large leading-edge radius (see fig. 2(e)) improved the stability at the stall but, as shown in figure 53, not sufficiently to overcome the large destabilizing moment contribution of the horizontal tail in the high position.

The improvements in stability resulting from the use of these control devices confirm that the stability problems are associated with the vortex shed from the fixed-wing leading edge. These devices delay formation of this vortex and thus tend to alleviate the instability.

#### Maximum Lift

Trailing-edge flaps.- Figure 54 summarizes the effects of both single-slotted and double-slotted flap systems. The full-span double-slotted flap

had a 0.3 greater lift increment at zero angle of attack. For both full-span flaps  $Cl_{max}$  was essentially the same, with the double-slotted flap achieving  $Cl_{max}$  at  $15^\circ$  angle of attack,  $3^\circ$  earlier than the single-slotted flap. With part-span deflection (outboard flap undeflected) the  $40^\circ$  single-slotted flap achieved higher  $Cl_{max}$  than the  $50^\circ$  double-slotted flap partly because of a higher lift-curve slope. Tuft observations indicated that double-slotted flap effectiveness was reduced at higher angles of attack by the fixed-wing vortex effect.

Figure 55 shows the effects of the amount of flap-span deflected. Deflection of the outboard flap sections produced an increase in lift through nearly the entire range of lift coefficients, including  $Cl_{max}$ . However, the additional nose-down moment produced by the outboard flaps resulted in a trim requirement which, for all practical purposes, cancelled the advantage in maximum lift coefficient.

Leading-edge slats.— A limited program to optimize wing leading-edge slat deflection and gap size was conducted with the low-tail, high-aspect-ratio configuration (A<sub>1</sub>). Figure 56 presents a summary of the results at a wing sweepback of  $13-1/2^\circ$  with  $50^\circ$  full-span double-slotted flaps. The effects of these slat variables on maximum lift coefficient are shown and were used to tailor the slat geometry for subsequent testing.

#### Lateral-Directional Stability

No unusual lateral or directional stability characteristics were evident in any of the configurations tested (see figs. 10, 13, 36, and 41). The model had directional stability and positive effective dihedral up to the stall angle of attack.

#### SUMMARY OF RESULTS

1. The results show that all configurations tested, except one, were longitudinally unstable at high lift. The one configuration that essentially eliminated this instability at stall consisted of a drooped fixed-wing leading-edge with the high-aspect-ratio wing at  $25^\circ$  of wing sweepback, in conjunction with the low horizontal-tail position.

2. No solution to longitudinal instability was achieved with the horizontal tail in any other than the low position (10 percent of the  $25^\circ$  sweep  $\bar{c}$  below the wing chord plane).

3. Results indicate that, for the low-speed configuration, reducing wing sweepback below  $25^{\circ}$  yielded no appreciable benefit in terms of a usable maximum lift coefficient (or that  $C_L$  at which longitudinal instability occurs).

*"The aeronautical and space activities of the United States shall be conducted so as to contribute . . . to the expansion of human knowledge of phenomena in the atmosphere and space. The Administration shall provide for the widest practicable and appropriate dissemination of information concerning its activities and the results thereof."*

—NATIONAL AERONAUTICS AND SPACE ACT OF 1958

## NASA SCIENTIFIC AND TECHNICAL PUBLICATIONS

**TECHNICAL REPORTS:** Scientific and technical information considered important, complete, and a lasting contribution to existing knowledge.

**TECHNICAL NOTES:** Information less broad in scope but nevertheless of importance as a contribution to existing knowledge.

**TECHNICAL MEMORANDUMS:** Information receiving limited distribution because of preliminary data, security classification, or other reasons.

**CONTRACTOR REPORTS:** Technical information generated in connection with a NASA contract or grant and released under NASA auspices.

**TECHNICAL TRANSLATIONS:** Information published in a foreign language considered to merit NASA distribution in English.

**TECHNICAL REPRINTS:** Information derived from NASA activities and initially published in the form of journal articles.

**SPECIAL PUBLICATIONS:** Information derived from or of value to NASA activities but not necessarily reporting the results of individual NASA-programmed scientific efforts. Publications include conference proceedings, monographs, data compilations, handbooks, sourcebooks, and special bibliographies.

*Details on the availability of these publications may be obtained from:*
